Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.
Dynamically modulating the surface plasmon resonance of doped semiconductor nanocrystals

Abstract

Localized surface plasmon absorption features arise at high doping levels in semiconductor nanocrystals, appearing in the near infrared range. Here we show that the surface plasmons of tin-doped indium oxide nanocrystal films can be dynamically and reversibly tuned by post-synthetic electrochemical modulation of the electron concentration. Without ion intercalation and the associated material degradation, we induce a > 1200 nm shift in the plasmon wavelength and a factor of nearly three change in the carrier density.

Keywords: surface plasmon, nanocrystal, indium tin oxide, spectroelectrochemistry, doping

Main text

Localized surface plasmon resonance (LSPR) features of metallic nanostructures have been leveraged for sensors, surface enhanced spectroscopy, and light-trapping in photovoltaic cells(1-5). Unlike metals, plasmon resonance frequencies of doped
semiconductors can be modified by changing the material's composition, creating new opportunities for plasmonic manipulation of light. In fact, well-defined LSPR features have recently been observed in the optical (infrared) spectra of highly doped semiconductor nanocrystals (NCs), especially transparent conducting oxides such as tin-doped indium oxide (ITO)(6-8). These optical characteristics are of great interest since the position of the plasmon peak can be adjusted on the basis of the chemical doping level. However, chemical tuning of the plasmon is fixed by the composition of the material, which cannot generally be dynamically modified. While it was shown very recently that the LSPR of copper deficient Cu$_2$S and Cu$_2$Se NCs shifts in response to oxidizing or reducing chemical treatments, this composition-driven optical response relies on the unusually high mobility of Cu$^+$ ions and the mechanisms for reversing oxidative doping remain uncertain (9,10).

Here, we show that the surface plasmon resonance of ITO NC films can be dynamically tuned through fully reversible electrochemical doping, hence realizing the promise of electrical manipulation of semiconductor LSPR features. Electrochemical doping of CdSe NC films was previously shown to bleach the exciton peak at the onset of the visible band gap absorption and to introduce a new intraband absorption peak in the far infrared region(11,12). However, the LSPR modulation of our ITO NCs is a collective response of the free electrons, more analogous to the electrochemical response of Au or Ag LSPR(13,14). In such metal nanostructures, acute screening by a high background charge density limits the shift of the LSPR peak to 10 or 20 nm, at most. Here, we show that the ITO NC LSPR can shift dynamically across a range covering much of the near infrared (NIR) spectrum (including telecommunications wavelengths), opening the door to potential applications including controlling optical coupling into or out of nanoplasmatic devices or tuning plasmonic enhancement of spectroscopic signatures(15). In this report, we elucidate the potential for these films to dynamically modulate transmittance of solar infrared radiation. Considering their excellent visible transparency, such modulation offers a unique opportunity for a dynamic coating on advanced, energy-saving "smart windows."
To prepare these coatings, we first synthesized colloidal ITO NCs of variable size and doping level by balancing precursor reactivity and adjusting the indium and tin content in the feedstock (Fig. 1a-d, Supporting Fig. S1, S2, and Table S1). Our modifications of literature procedures(6,7) are described in the Supplementary Information. The resulting NCs are capped with organic ligands that facilitate dispersion in hydrophobic solvents. Transmission spectra of these dispersions reveal well-defined LSPR peaks whose position relates to the doping level (Fig. 1e). The frequency of the LSPR ($\omega_{LSP}$) is proportional to the bulk plasmon frequency ($\omega_P$), which varies as square root of the free carrier concentration ($n$)(1).

$$\omega_{LSP} \propto \omega_P = \sqrt{\frac{n\epsilon^2}{m^*\epsilon_0}}$$

(1)

Here, our synthetic variation of the tin content manipulates $n$, which in turn adjusts $\omega_{LSP}$. The LSPR resonance frequency varies much less strongly with size(1), which is therefore available as a pseudo-independent variable in tuning the properties of our active coatings.

To enable dynamic modulation of the LSPR, the NCs were processed into electrically conducting films, approximately 150 nm thick (Fig. 2a). Deposition of uniform, non-scattering films by spin coating from a mixture of hexane and octane was facilitated by the hydrocarbon ligands which cap the surfaces of the NC. However, these ligands form highly insulating barriers between adjacent NCs and must be eliminated. Simple air annealing caused the LSPR feature to disappear, consistent with the trapping of free carriers by filling structural oxygen vacancies(16). Instead, we displaced the original, bulky oleic acid ligands with small molecules by submerging the NC film in a solution of formic acid, resulting in mass-action driven ligand exchange within the film(17). Formic acid is volatile and can be desorbed by low temperature annealing in an inert environment (Supporting Fig. S3). The sheet resistance of the film drops with annealing temperature up to 500 °C, but it is already sufficiently low following a 200°C anneal to conduct in-plane over
centimeter-scale sample dimensions (Supporting Fig. S4). For subsequent investigations, we annealed the films at 250°C, which reproducibly gave well-conducting films with a low thermal budget.

At each stage of film deposition and processing, the absorption peak shifted to longer wavelength (Fig. 2b), raising questions about possible changes in the free carrier concentration and the structure of the NC films. First, we verified that the crystallite size remains fixed; the x-ray diffraction pattern and peak widths remain unchanged following annealing (Supporting Fig. S5). Next, we employed an extended Drude model to fit the optical transmission spectra. The model (discussed more extensively in the Supporting Information) considers possible changes in the carrier concentration, the dielectric environment, the volume fraction of the NCs, as well as variations in damping that might arise as the NC surfaces are chemically modified(18,19). Excellent fits are achieved to the experimental data (Supporting Fig. S6) from which we conclude that the shifts in the absorption peak can be primarily ascribed to an increasing ITO volume fraction from extremely low in the solvent dispersion, to 0.35 in the as-deposited film containing oleic acid ligands, and finally to 0.47 in the ligand exchanged and annealed film (Supporting Table S2). The increasing ITO volume fraction both enhances coupling between adjacent NCs, which are brought into more intimate contact with each processing step, and raises the average dielectric environment surrounding the NCs(20,21). Notably, there is very little change in the plasmon frequency – and therefore in the free carrier concentration – during film processing.

To actively modulate their surface plasmon resonance, the NC films were positioned as the working electrode in an electrochemical cell and in situ transmission spectra recorded as a function of the applied potential. Due to the onset of strong absorption bands of the electrolyte, the in situ measurements were limited to a spectral window of 400-2200 nm. The optical spectrum of the film at its open circuit voltage shows minimal change compared to its spectrum in an air environment, consistent with the change in dielectric environment and indicating that no chemical reactions occur at
the NC surface (Supporting Fig. S7). As we apply a negative bias, the SPR peak shifts to higher energy and becomes more intense (Fig. 3a). Both changes are consistent with the modulation of the free carrier concentration, $n$, which would shift the plasmon resonance frequency, as in equation (1), and increase the extinction at the LSPR peak proportionally(1). This result stands in stark contrast to earlier reports of the spectroelectrochemical response of nanocrystalline Sb-SnO$_2$ films(22,23). In that case, the applied potential induced negligible shift, only changing the intensity of the plasmon absorption feature. It was suggested that a high density of surface traps led to a strong depletion of free carriers near the surface and a variation in the thickness of this depletion region was proposed to account for the nearly constant $\omega_{LSP}$ even as electrons were injected or extracted. The strong shifting of the LSPR peak we observe suggests that our ITO NC films are relatively free of such surface defect sites.

In fact, we propose that the modulation of the surface plasmon resonance in our ITO NC films is more analogous to that found in metallic nanostructures(14) and is related to that demonstrated recently at the planar interface of ITO with a dielectric layer(24). In the latter case, the free carrier concentration in a thin (~5 nm) accumulation region was modulated by applying a potential between the ITO film and a counter electrode on the opposite side of the dielectric layer. Since we observe plasmon resonance shifts to both shorter and longer wavelength than the initial state, we suggest that accumulation and depletion regions, respectively, are formed near the surface of the NCs. This hypothesis predicts greater modulation for smaller NCs, whose entire volume can lie within the strongly modulated accumulation/depletion region. Indeed, comparing NCs of similar chemical doping level, the magnitude of the change in extinction between the two extremes of applied bias tracks with NC diameter (Fig. 3b). Thus, for small, highly doped NCs we can strongly modulate the plasmon frequency, and the associated free carrier concentration, throughout the volume of each NC and of the overall film.
We can quantitively evaluate these dynamic changes by fitting the spectra of the electrochemically modulated NC film using the extended Drude model (again, discussed in the Supporting Information). Absolute transmittance of the entire electrochemical cell is used for the modeling in order to properly account for the interfaces. For the free parameters associated with the ITO nanocrystal film, confidence in the values was evaluated by starting with various initial conditions and keeping all parameters within physically reasonable bounds. We found that $\omega_p$ converged reliably to near the same value regardless of the starting conditions, so that $\omega_p$ and $n$ could be extracted as a function of the bias applied in the electrochemical cell (Fig. 3c and Supporting Fig. S8). The free carrier concentration changes by nearly a factor of three, resulting in almost a factor of two change in the plasmon frequency between the two extremes.

Such large changes in plasmon resonance could be applicable to micron-scale plasmonic devices, or might even be leveraged at the single-nanocrystal level\cite{2,14}. Unlike the case of a planar ITO film, the transmission through the NC film changes dramatically since there is far greater surface area. We note that the contrast ratio for transmittance of 1.55 $\mu$m light, relevant to telecommunications, exceeds 12:1 ($\sim$11 dB) without any optimization. By adjusting the chemical doping level, modulation of any specific wavelength in the NIR could be maximized.

The electrochemical modulation of transmittance through thin films, as demonstrated here, is of particular interest for dynamic "smart window" applications. In this case, the NC film is effectively part of a macroplasmonic device, operating on nanoplasmonic principles. The heat load derived from solar infrared radiation could be dynamically modulated in response to the changing outdoor environment, while visible light transmittance is maintained for daylighting use\cite{25}. In contrast, the conventional electrochromic window coatings reported in the literature and now emerging on the market most strongly modulate visible light, with a more modest dynamic range for NIR transmittance\cite{26}. 
In order to explore the potential performance of a dynamic, spectrally-selective window coating based on LSPR modulation, we measured the dynamic transmittance of NC films as a function of film thickness (Fig. 4a). In thicker films the surface plasmon absorption becomes saturated, providing a sharper edge between high and low transmission and minimizing the NIR transmittance at negative bias. However, the maximum NIR transmittance at positive bias and the visible transmittance, in general, are adversely affected. These trade-offs lead to an optimal thickness at which the dynamic range of NIR transmittance is maximized, with minimal impact on visible transmittance.

The implications of these dynamic optical properties for smart window performance can be evaluated by convoluting the transmittance spectra of the 310 nm thick NC film with the solar spectrum (Fig. 4b). The shaded regions show the portion of the solar spectrum transmitted when the film is in the "bleached" state (positive bias) and "colored" state (negative bias). It is apparent that NIR light is strongly modulated while visible light is largely transmitted in both states. Integrating these curves, we find a 21% difference in transmittance overall and 35% difference in transmittance of the NIR portion of the solar spectrum between the two states. This already represents a substantial modulation of solar heating for a window, with further gains potentially available by additional optimization of nanocrystal size, chemical doping level, coupling, and film thickness. Meanwhile, there is only 6% modulation of the solar insolation visible to the human eye (Fig. 4c); even in the colored state, over 92% of this light remains available to off-set the need for electric lighting.

An important requirement of plasmonic switching, whether applied to macro- or micro-scale devices, is stability under repeated cycling. In fact, this is a critical factor limiting the application of many otherwise promising electrochromic technologies to smart window coatings(26). Preliminary durability testing of our NC films shows virtually no change in their electrochemical properties over multiple charge-
discharge cycles (Supporting Fig. S9), and CdSe NC films have been cycled at least 10,000 times without degradation(12). The stability of our films is consistent with the mechanism proposed above in which an accumulation/depletion layer is reversibly switched near the NC surface. Unlike a conventional electrochromic coating(26) or the plasmonic Cu$_2$S and Cu$_2$Se NCs recently reported(9,10), this operating principle does not involve cation migration through the active material. In other words, the switching is capacitive and our coating operates like the electrode of a supercapacitor whereas conventional electrochromic films are more analogous to battery electrodes.

The hypothesis of capacitive switching was tested by comparing the spectroelectrochemical response of a NC film in Li$^+$ containing electrolyte (used in all the experiments described thus far) to its behavior in a tetrabutylammonium (TBA$^+$) electrolyte. Unlike Li$^+$, TBA$^+$ is physically too large to intercalate, leaving only capacitive contributions(23). The charging profile, recorded by cyclic voltammetry is similar for the two electrolytes, and the total charge injected and extracted is nearly identical (Supporting Fig. S10). Even more telling, the NIR optical responses are indistinguishable (Supporting Fig. S11). Clearly, intercalation is not required to achieve the extreme modulation of plasmon resonance that we observe. A principle degradation pathway for battery and electrochromic electrode materials, namely strain from repeated intercalation and deintercalation(26), is thus completely circumvented by the capacitive operating mechanism. The coloration efficiency is also improved by several fold over conventional electrochromic films (Supporting Fig. S12).

The efficacy of compensating injected carriers capacitively, without intercalation, is not limited to the choice of ITO as an electrode material; it is rather a direct consequence of nanostructuring on the single-digit nanometer scale. Any material which undergoes a change in optical properties upon charging and discharging, including other plasmonic NCs, but also conventional electrochromic materials like WO$_3$, could, in principle, be operated in this manner(27). Hence, our results suggest
a new paradigm for the design of nanocrystal-based electrochromic electrodes that are robust to cycling, greatly expanding options for material selection to achieve targeted optical response characteristics for smart windows and other applications of optical modulation.
